INTRODUCTION: On January 26, 2017, FDACS-DPI received a request from Dr. Julien Beuzelin (UF/IFAS Belle Glade) for information concerning the identity of a thrips found on sugarcane in Glades and Hendry counties in South Florida. The leaves on which the thrips were collected showed evidence of damage, and the question was whether the damage could have been caused by the thrips. Samples of thrips were received at FDACS-DPI in Gainesville on January 31, 2017, and on February 2, 2017, the insects were identified as the sugarcane thrips *Fulmekiola serrata*. The sugarcane thrips is native to East Asia, but has been introduced into South Africa, Madagascar and some of the West Indies, including Cuba and Puerto Rico. The species completes its life cycle in a number of grass species, but most frequently it is found on sugarcane. About half of the individuals submitted to FDACS-DPI for identification were larvae or pupae, indicating that the species is actively reproducing. This is an important pest of sugarcane that under some conditions may reduce sugarcane sucrose yield by up to 24 percent (Way et al. 2010).

DAMAGE: Damage is caused directly by thrips feeding on leaves. The leaves of heavily infested plants have brown, dried leaf tips (Fig. 1) and margins (Fig. 2), whereas other parts of the leaves may show multiple yellowish blotches and streaks (Fig. 3).

IDENTIFICATION: The sugarcane thrips is a small but very distinctive species. Adult females grow to 1.1 mm, whereas males are around 0.9 mm long. Both sexes are brown, although males (Fig. 4) tend to be darker than females (Fig. 5); the ocelli are orange (Fig. 6) and the antennae are dark brown or black, except for the third, fourth and sometimes fifth segments, which are light brown or white (Fig. 6); wings are mostly dusky black, with a light or white base. The dark first and second antennal segments distinguish *F. serrata* from the superficially similar *Frankliniella williamsi* (Hood), in which the first two antennal segments are light instead of dark. Additional information on the sugarcane thrips can be found in Moritz et al. (2017) at: http://thripsnet.zoologie.uni-halle.de/key-server-neu/data/0a0b0a0e-0d03-4106-8306-08060a080902/media/Html/Fulmekiola%20serrata.html

MONITORING: Sugarcane thrips can be sampled using either blue or clear sticky traps and by direct examination of leaf spindles. Traps set 50 to 120 cm above ground may be used for monitoring. The presence of a few individuals on the traps may indicate an infestation and should be followed by direct examination of leaf spindles (Way et al 2011).
